Dear Editor,

The number of confirmed cases of the 2019 novel coronavirus (COVID-19) reported to the WHO continues to rise worldwide. The outbreak of the novel coronavirus (COVID-19) is being regarded a serious threat to the global community [1]. On March 17, 2020, the total number of confirmed cases was 179,111 globally, with 7,426 death. The number of infected nations has increased to 158 countries. The mortality rate of this novel virus is 3–4% (dividing the total death numbers by the total recorded cases) (Table 1) [2].

The most common infected persons with COVID-19 were men with chronic pulmonary or cardiovascular disorders, hypertension, and diabetes. Infected individuals have a fever, cough with sputum, headache, and diarrhea. Renal failure may be one of the viral complications [3].

Zhao et al. [4] reported that individuals with blood group type A are at high risk to get COVID-19 compared with other blood groups, whereas people with blood group type O have a lower risk for acquiring infection compared with others [4]. This emergent finding is based on comparing the blood group of 2,173 confirmed patients with COVID-19 (including 206 deceased cases) in China with that in normal people from a similar area.

The tested ABO blood group of 3,694 normal individuals showed distribution of 32.16%, 24.90%, 9.10%, and 33.84%, for A, B, AB, and O, respectively, whereas of 1,775 persons infected with COVID-19 appeared as 25.80%, 10.03%, 26.42%, and 37.75% for O, AB, B, and A, respectively. The proportion of blood group A in patients with COVID-19 was significantly higher than that in normal people, being 37.75% in the former versus 32.16% in the latter (P < 0.001). On comparison of blood group A in normal people (32.16%) with patients with COVID-19 (37.75%), it was significantly higher in patients with COVID-19 (P < 0.001), whereas the blood group O in patients with COVID-19 was clearly lower than that in normal persons, being 25.80% in the patients versus 33.84% in the normal people (P < 0.001). The risk among blood group A individuals was higher for being infected with COVID-19, with an odds ratio (OR) of 1.279; on the contrary, there was decreased risk among those with blood group O for COVID-19, with an OR of 0.680, compared with other blood groups.

In the 206 deceased patients, ABO group distribution was also observed. Blood group A individuals have a higher risk of infection compared with blood group O in the dead individuals; the presence of O, AB, B, and A in the total investigated dead patients was 25.24%, 9.22%, 24.27%, and 41.26%, respectively. Blood group O was associated with a lower risk of death compared with non-O groups, with an OR of 0.660. On the contrary, blood group A was associated with a higher risk of death compared with non-A groups, with an OR of 1.482 (Fig. 1).

Figure 1: Distribution of ABO blood group in 206 deceased patients with COVID-19
To conclude, the ABO blood groups displayed different associated risks for the infection with COVID-19. Blood group A was significantly associated with an increased risk, whereas blood group O was associated with a decreased risk, thus demonstrating that the ABO blood type is a biomarker for differential susceptibility of COVID-19. People with blood group A might require particularly enhanced personal protection to diminish the chance of infection and should receive more vigilant surveillance and aggressive management.
